# **Quicksort**

Quicksort, like merge sort, applies the divide-and-conquer paradigm introduced in Section 2.3.1. Here is the three-step divide-and-conquer process for sorting a typical subarray  $A[p..r]$ :

**Divide:** Partition (rearrange) the array  $A[p..r]$  into two (possibly empty) subarrays  $A[p..q - 1]$  and  $A[q + 1..r]$  such that each element of  $A[p .. q - 1]$  is less than or equal to  $A[q]$ , which is, in turn, less than or equal to each element of  $A[q + 1..r]$ . Compute the index  $q$  as part of this partitioning procedure.

**Conquer:** Sort the two subarrays  $A[p..q - 1]$  and  $A[q + 1..r]$  by recursive calls to quicksort.

**Combine:** Because the subarrays are already sorted, no work is needed to combine them: the entire array  $A[p..r]$  is now sorted.

The following procedure implements quicksort:

QUICKSORT( $A, p, r$ )

```
1  if  $p < r$ 
2       $q = \text{PARTITION}(A, p, r)$ 
3      QUICKSORT( $A, p, q - 1$ )
4      QUICKSORT( $A, q + 1, r$ )
```

To sort an entire array  $A$ , the initial call is  $\text{QUICKSORT}(A, 1, A.length)$ .

### Partitioning the array

The key to the algorithm is the PARTITION procedure, which rearranges the subarray  $A[p \dots r]$  in place.

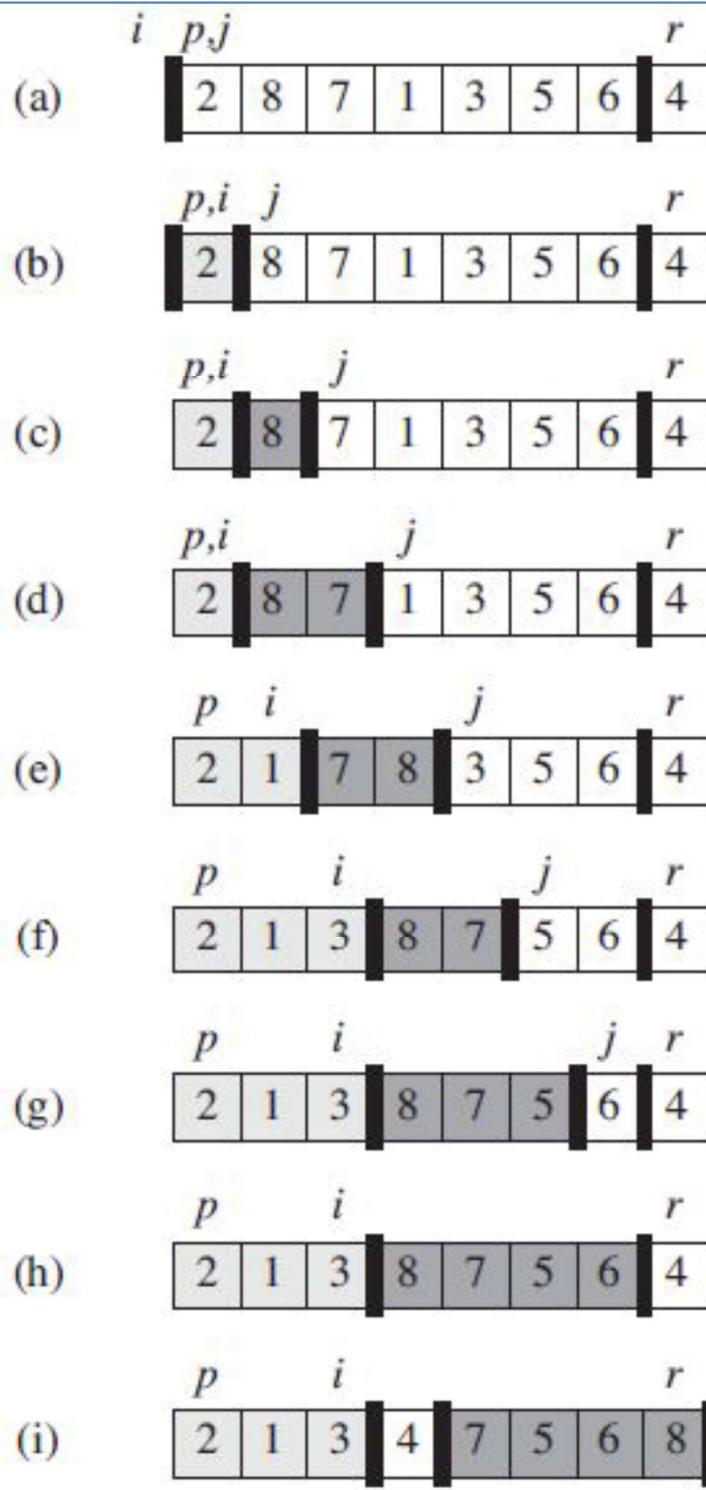

PARTITION( $A, p, r$ )

```
1   $x = A[r]$ 
2   $i = p - 1$ 
3  for  $j = p$  to  $r - 1$ 
4      if  $A[j] \leq x$ 
5           $i = i + 1$ 
6          exchange  $A[i]$  with  $A[j]$ 
7  exchange  $A[i + 1]$  with  $A[r]$ 
8  return  $i + 1$ 
```

Figure 7.1 shows how PARTITION works on an 8-element array. PARTITION always selects an element  $x = A[r]$  as a *pivot* element around which to partition the subarray  $A[p..r]$ . As the procedure runs, it partitions the array into four (possibly empty) regions. At the start of each iteration of the **for** loop in lines 3–6, the regions satisfy certain properties, shown in Figure 7.2. We state these properties as a loop invariant:

At the beginning of each iteration of the loop of lines 3–6, for any array index  $k$ ,

1. If  $p \leq k \leq i$ , then  $A[k] \leq x$ .
2. If  $i + 1 \leq k \leq j - 1$ , then  $A[k] > x$ .
3. If  $k = r$ , then  $A[k] = x$ .

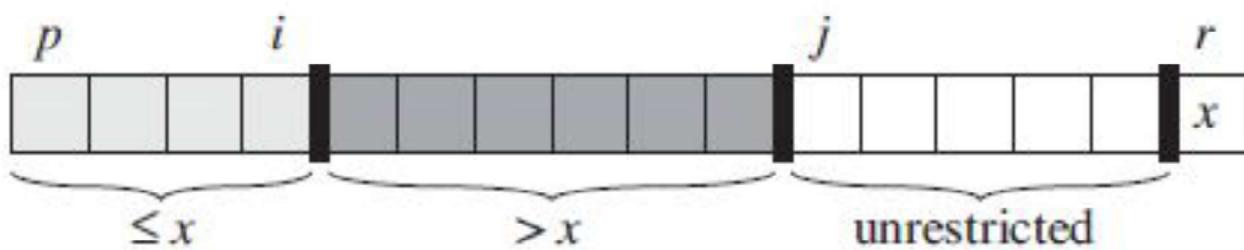

**PARTITION( $A, p, r$ )**

```

1   $x = A[r]$ 
2   $i = p - 1$ 
3  for  $j = p$  to  $r - 1$ 
4    if  $A[j] \leq x$ 
5       $i = i + 1$ 
6      exchange  $A[i]$  with  $A[j]$ 
7  exchange  $A[i + 1]$  with  $A[r]$ 
8  return  $i + 1$ 

```

**Figure 7.1** The operation of PARTITION on a sample array. Array entry  $A[r]$  becomes the pivot element  $x$ . Lightly shaded array elements are all in the first partition with values no greater than  $x$ . Heavily shaded elements are in the second partition with values greater than  $x$ . The unshaded elements have not yet been put in one of the first two partitions, and the final white element is the pivot  $x$ . (a) The initial array and variable settings. None of the elements have been placed in either of the first two partitions. (b) The value 2 is “swapped with itself” and put in the partition of smaller values. (c)–(d) The values 8 and 7 are added to the partition of larger values. (e) The values 1 and 8 are swapped, and the smaller partition grows. (f) The values 3 and 7 are swapped, and the smaller partition grows. (g)–(h) The larger partition grows to include 5 and 6, and the loop terminates. (i) In lines 7–8, the pivot element is swapped so that it lies between the two partitions.

**Figure 7.2** The four regions maintained by the procedure PARTITION on a subarray  $A[p..r]$ . The values in  $A[p..i]$  are all less than or equal to  $x$ , the values in  $A[i + 1..j - 1]$  are all greater than  $x$ , and  $A[r] = x$ . The subarray  $A[j..r - 1]$  can take on any values.

# Running Time

The final two lines of PARTITION finish up by swapping the pivot element with the leftmost element greater than  $x$ , thereby moving the pivot into its correct place in the partitioned array, and then returning the pivot's new index. The output of PARTITION now satisfies the specifications given for the divide step. In fact, it satisfies a slightly stronger condition: after line 2 of QUICKSORT,  $A[q]$  is strictly less than every element of  $A[q + 1..r]$ .

The running time of PARTITION on the subarray  $A[p..r]$  is  $\Theta(n)$ , where  $n = r - p + 1$  (see Exercise 7.1-3).

# Performance of quicksort

- The running time of quicksort depends on whether the partitioning is balanced or unbalanced, which in turn depends on which elements are used for partitioning.
- If the partitioning is balanced, the algorithm runs asymptotically as fast as merge sort.
- If the partitioning is unbalanced, however, it can run asymptotically as slowly as insertion sort.
- Here, we shall informally investigate how quicksort performs under the assumptions of balanced versus unbalanced partitioning.

## Worst-case partitioning

The worst-case behavior for quicksort occurs when the partitioning routine produces one subproblem with  $n - 1$  elements and one with 0 elements. (We prove this claim in Section 7.4.1.) Let us assume that this unbalanced partitioning arises in each recursive call. The partitioning costs  $\Theta(n)$  time. Since the recursive call on an array of size 0 just returns,  $T(0) = \Theta(1)$ , and the recurrence for the running time is

$$\begin{aligned} T(n) &= T(n - 1) + T(0) + \Theta(n) \\ &= T(n - 1) + \Theta(n). \end{aligned}$$

Intuitively, if we sum the costs incurred at each level of the recursion, we get an arithmetic series (equation (A.2)), which evaluates to  $\Theta(n^2)$ . Indeed, it is straightforward to use the substitution method to prove that the recurrence  $T(n) = T(n - 1) + \Theta(n)$  has the solution  $T(n) = \Theta(n^2)$ . (See Exercise 7.2-1.)

Thus, if the partitioning is maximally unbalanced at every recursive level of the algorithm, the running time is  $\Theta(n^2)$ . Therefore the worst-case running time of quicksort is no better than that of insertion sort. Moreover, the  $\Theta(n^2)$  running time occurs when the input array is already completely sorted—a common situation in which insertion sort runs in  $O(n)$  time.

## Best-case partitioning

In the most even possible split, PARTITION produces two subproblems, each of size no more than  $n/2$ , since one is of size  $\lfloor n/2 \rfloor$  and one of size  $\lceil n/2 \rceil - 1$ . In this case, quicksort runs much faster. The recurrence for the running time is then

$$T(n) = 2T(n/2) + \Theta(n),$$

where we tolerate the sloppiness from ignoring the floor and ceiling and from subtracting 1. By case 2 of the master theorem (Theorem 4.1), this recurrence has the solution  $T(n) = \Theta(n \lg n)$ . By equally balancing the two sides of the partition at every level of the recursion, we get an asymptotically faster algorithm.

# Heap Sort

# Heap

The *(binary) heap* data structure is an array object that we can view as a nearly complete binary tree (see Section B.5.3), as shown in Figure 6.1. Each node of the tree corresponds to an element of the array. The tree is completely filled on all levels except possibly the lowest, which is filled from the left up to a point. An array  $A$  that represents a heap is an object with two attributes:  $A.length$ , which (as usual) gives the number of elements in the array, and  $A.heap-size$ , which represents how many elements in the heap are stored within array  $A$ . That is, although  $A[1 \dots A.length]$  may contain numbers, only the elements in  $A[1 \dots A.heap-size]$ , where  $0 \leq A.heap-size \leq A.length$ , are valid elements of the heap. The root of the tree is  $A[1]$ , and given the index  $i$  of a node, we can easily compute the indices of its parent, left child, and right child:

# Heap

PARENT( $i$ )

1   **return**  $\lfloor i/2 \rfloor$

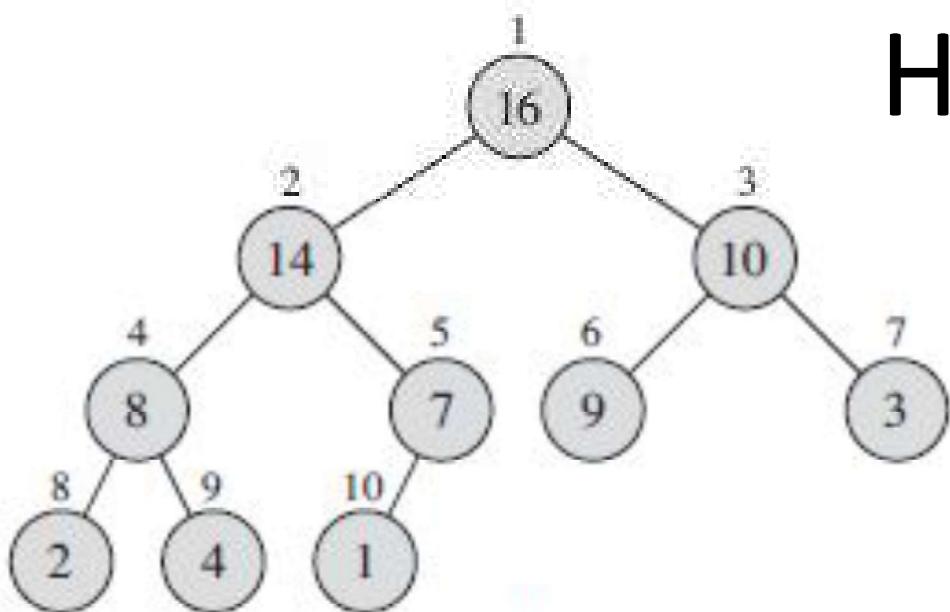

LEFT( $i$ )

1   **return**  $2i$

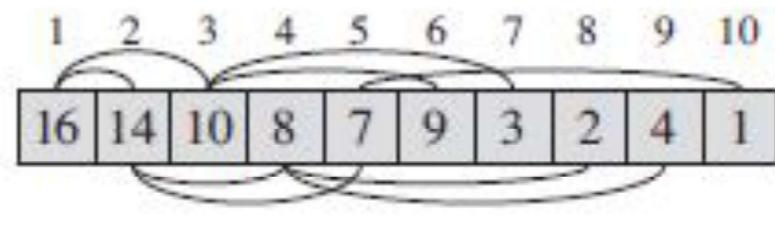

RIGHT( $i$ )

1   **return**  $2i + 1$

# Heap

(a)

(b)

**Figure 6.1** A max-heap viewed as (a) a binary tree and (b) an array. The number within the circle at each node in the tree is the value stored at that node. The number above a node is the corresponding index in the array. Above and below the array are lines showing parent-child relationships; parents are always to the left of their children. The tree has height three; the node at index 4 (with value 8) has height one.

# Heap

- There are two kinds of binary heaps: **max-heaps** and **min-heaps**. In both kinds, the values in the nodes satisfy a heap property, the specifics of which depend on the kind of heap.
- In a **max-heap**, the **max-heap** property is that for every node  $i$  other than the root,

$$A[\text{PARENT}(i)] \geq A[i],$$

- That is, the value of a node is at most the value of its parent. Thus, the largest element in a **max-heap** is stored at the **root**, and the subtree rooted at a node contains values no larger than that contained at the node itself.

# Heap

- A *min-heap is organized in* the opposite way; the *min-heap property is that for every node  $i$  other than the root,*

$$A[\text{PARENT}(i)] \leq A[i].$$

- The smallest element in a min-heap is at the root.
- For the heap-sort algorithm, we use max-heaps. Min-heaps commonly implement priority queues.
- We shall be precise in specifying whether we need a max-heap or a min-heap for any particular application, and when properties apply to either max-heaps or min-heaps, we just use the term “heap.”

# Heap

- Viewing a heap as a tree, we define the *height of a node in a heap to be the* number of edges on the longest simple downward path from the node to a leaf, and we define the height of the heap to be the height of its root.

# Heap

- The **MAX-HEAPIFY** procedure, which runs in  $O(\lg n)$  time, is the key to maintaining the max-heap property.
- The **BUILD-MAX-HEAP** procedure, which runs in linear time, produces a max-heap from an unordered input array.
- The **HEAPSORT** procedure, which runs in  $O(n \lg n)$  time, sorts an array in place.
- The **MAX-HEAP-INSERT**, **HEAP-EXTRACT-MAX**, **HEAP-INCREASE-KEY**, and **HEAP-MAXIMUM** procedures, which run in  $O(\lg n)$  time, allow the heap data structure to implement a priority queue.

# Maintaining the heap property

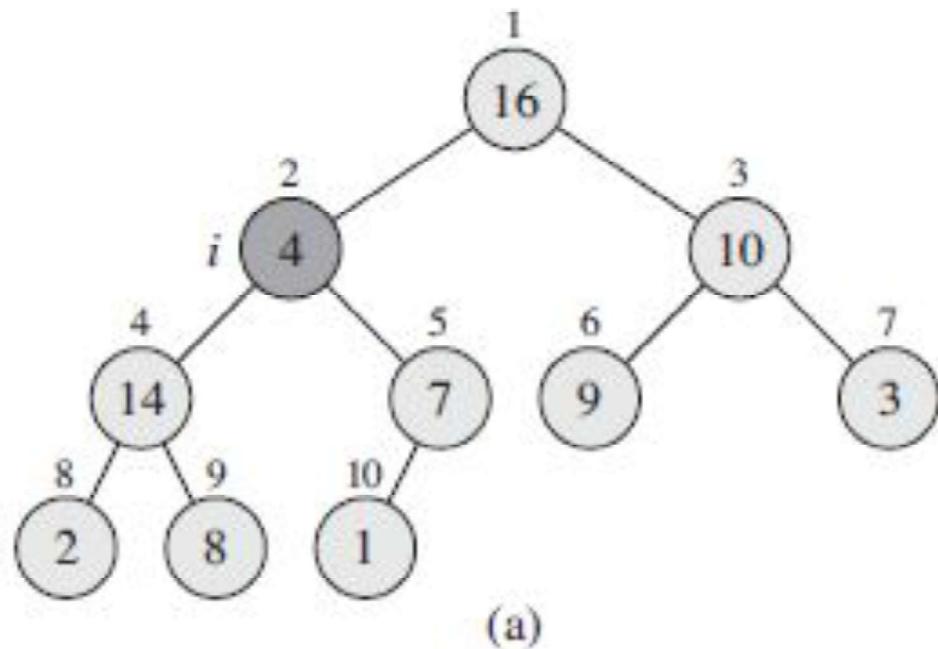

In order to maintain the max-heap property, we call the procedure **MAX-HEAPIFY**. Its inputs are an array  $A$  and an index  $i$  into the array. When it is called, **MAX-HEAPIFY** assumes that the binary trees rooted at  $\text{LEFT}(i)$  and  $\text{RIGHT}(i)$  are max-heaps, but that  $A[i]$  might be smaller than its children, thus violating the max-heap property. **MAX-HEAPIFY** lets the value at  $A[i]$  “float down” in the max-heap so that the subtree rooted at index  $i$  obeys the max-heap property.

**MAX-HEAPIFY**( $A, i$ )

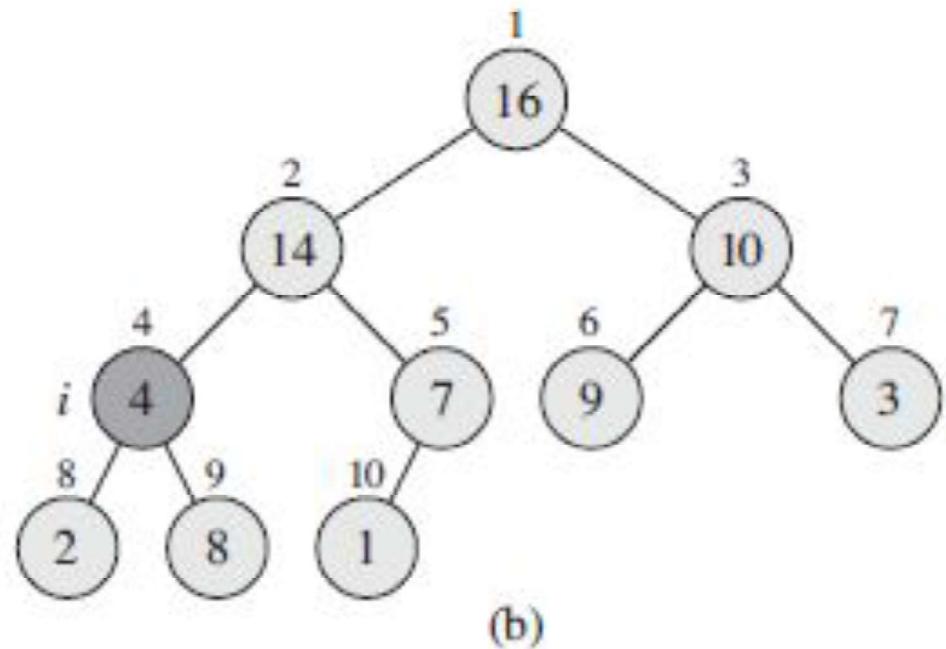

- 1  $l = \text{LEFT}(i)$
- 2  $r = \text{RIGHT}(i)$
- 3 **if**  $l \leq A.\text{heap-size}$  and  $A[l] > A[i]$ 
  - 4      $largest = l$
  - 5 **else**  $largest = i$
  - 6 **if**  $r \leq A.\text{heap-size}$  and  $A[r] > A[largest]$ 
    - 7      $largest = r$
    - 8 **if**  $largest \neq i$ 
      - 9         exchange  $A[i]$  with  $A[largest]$
    - 10         **MAX-HEAPIFY**( $A, largest$ )

Figure 6.2 illustrates the action of **MAX-HEAPIFY**. At each step, the largest of the elements  $A[i]$ ,  $A[\text{LEFT}(i)]$ , and  $A[\text{RIGHT}(i)]$  is determined, and its index is stored in *largest*. If  $A[i]$  is largest, then the subtree rooted at node  $i$  is already a max-heap and the procedure terminates. Otherwise, one of the two children has the largest element, and  $A[i]$  is swapped with  $A[\text{largest}]$ , which causes node  $i$  and its children to satisfy the max-heap property. The node indexed by *largest*, however, now has the original value  $A[i]$ , and thus the subtree rooted at *largest* might violate the max-heap property. Consequently, we call **MAX-HEAPIFY** recursively on that subtree.

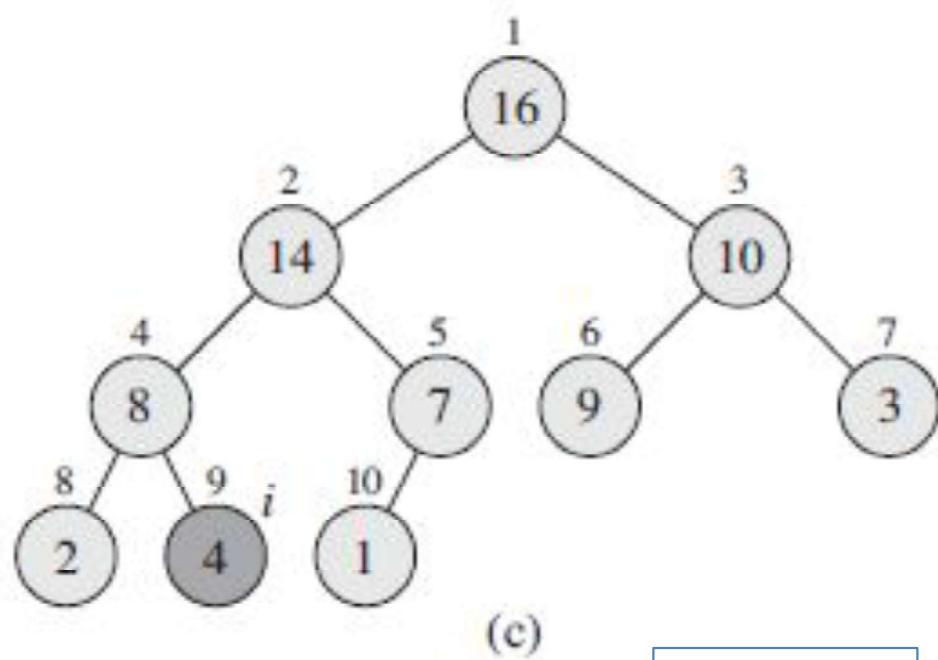

**Figure 6.2** The action of **MAX-HEAPIFY**( $A, 2$ ), where  $A.\text{heap-size} = 10$ . (a) The initial configuration, with  $A[2]$  at node  $i = 2$  violating the max-heap property since it is not larger than both children. The max-heap property is restored for node 2 in (b) by exchanging  $A[2]$  with  $A[4]$ , which destroys the max-heap property for node 4. The recursive call **MAX-HEAPIFY**( $A, 4$ ) now has  $i = 4$ . After swapping  $A[4]$  with  $A[9]$ , as shown in (c), node 4 is fixed up, and the recursive call **MAX-HEAPIFY**( $A, 9$ ) yields no further change to the data structure.

(a)

(b)

(c)

**Fig: 6.2**

**MAX-HEAPIFY( $A, i$ )**

- 1  $l = \text{LEFT}(i)$
- 2  $r = \text{RIGHT}(i)$
- 3 **if**  $l \leq A.\text{heap-size}$  and  $A[l] > A[i]$
- 4      $\text{largest} = l$
- 5 **else**  $\text{largest} = i$
- 6 **if**  $r \leq A.\text{heap-size}$  and  $A[r] > A[\text{largest}]$
- 7      $\text{largest} = r$
- 8 **if**  $\text{largest} \neq i$
- 9     exchange  $A[i]$  with  $A[\text{largest}]$
- 10    **MAX-HEAPIFY( $A, \text{largest}$ )**

# Running Time

The running time of **MAX-HEAPIFY** on a subtree of size  $n$  rooted at a given node  $i$  is the  $\Theta(1)$  time to fix up the relationships among the elements  $A[i]$ ,  $A[\text{LEFT}(i)]$ , and  $A[\text{RIGHT}(i)]$ , plus the time to run **MAX-HEAPIFY** on a subtree rooted at one of the children of node  $i$  (assuming that the recursive call occurs). The children's subtrees each have size at most  $2n/3$ —the worst case occurs when the bottom level of the tree is exactly half full—and therefore we can describe the running time of **MAX-HEAPIFY** by the recurrence

$$T(n) \leq T(2n/3) + \Theta(1).$$

# Building a heap

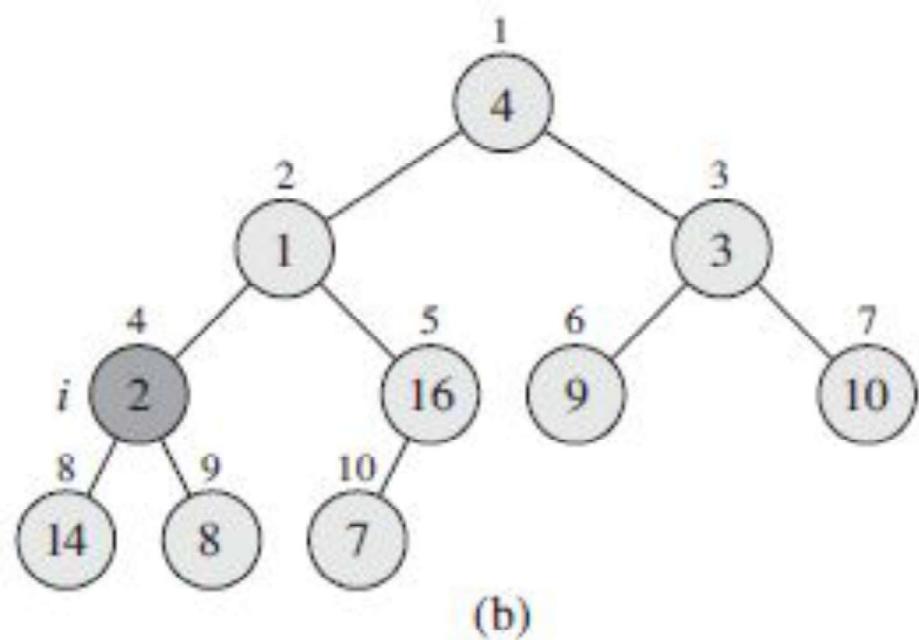

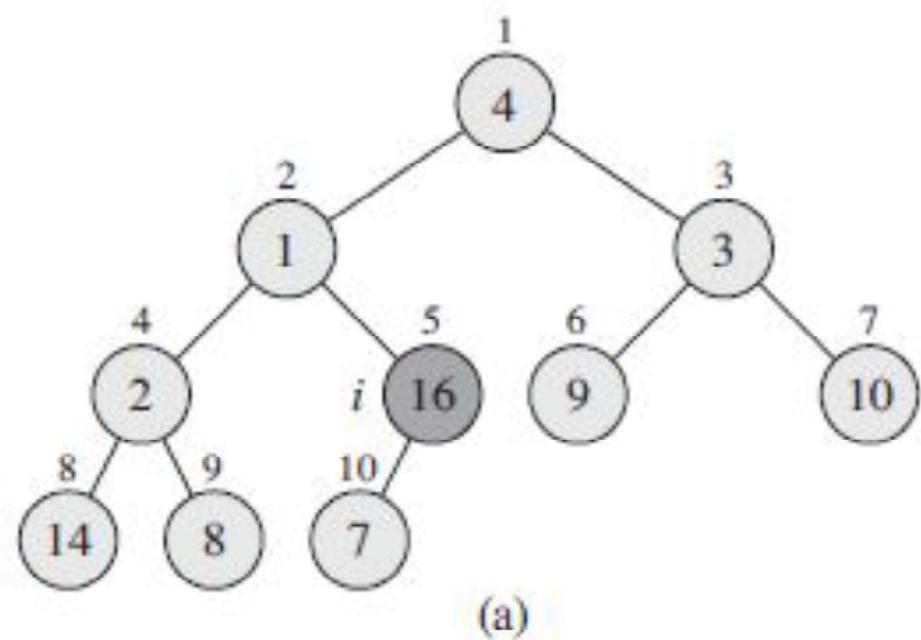

We can use the procedure **MAX-HEAPIFY** in a bottom-up manner to convert an array  $A[1..n]$ , where  $n = A.length$ , into a max-heap. By Exercise 6.1-7, the elements in the subarray  $A[(\lfloor n/2 \rfloor + 1)..n]$  are all leaves of the tree, and so each is a 1-element heap to begin with. The procedure **BUILD-MAX-HEAP** goes through the remaining nodes of the tree and runs **MAX-HEAPIFY** on each one.

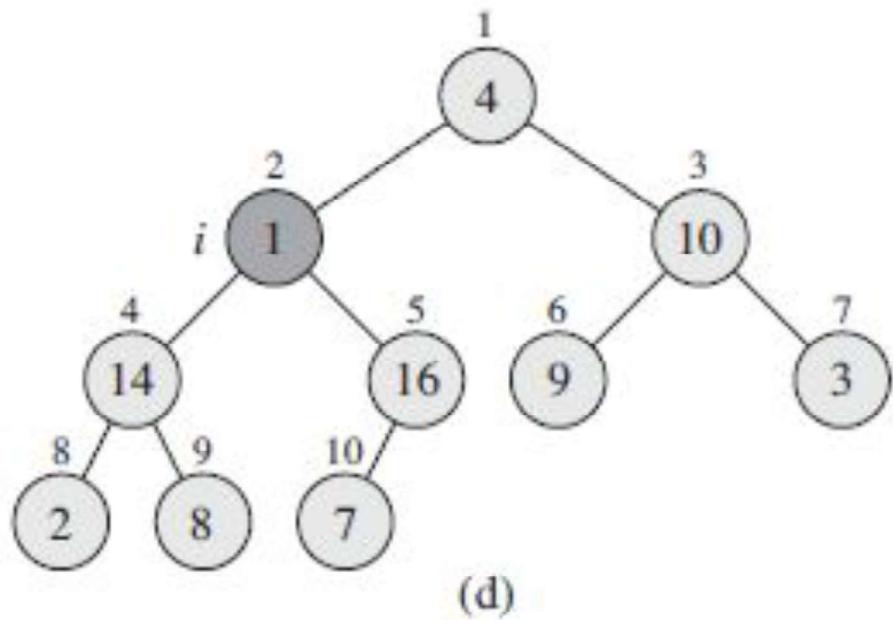

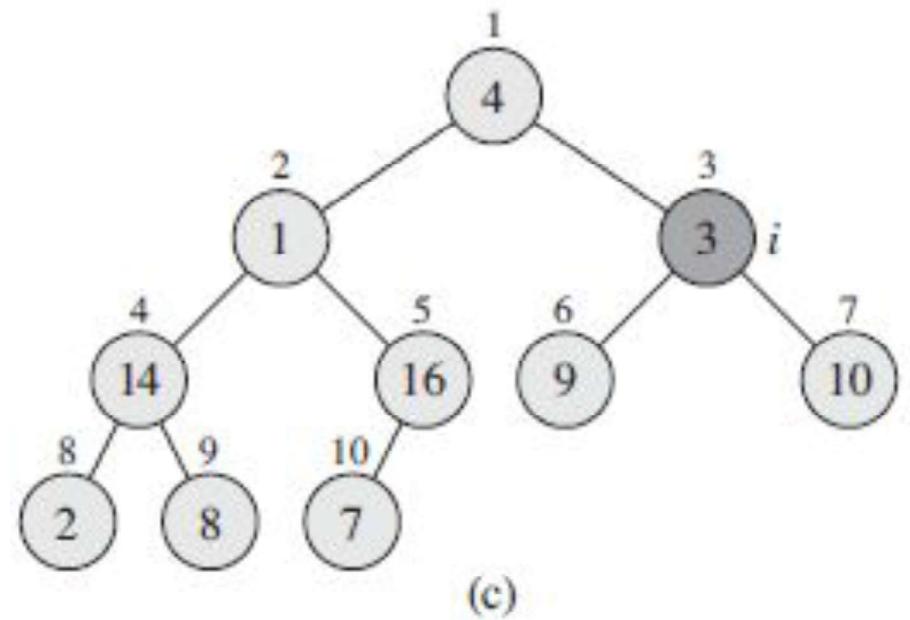

## **BUILD-MAX-HEAP( $A$ )**

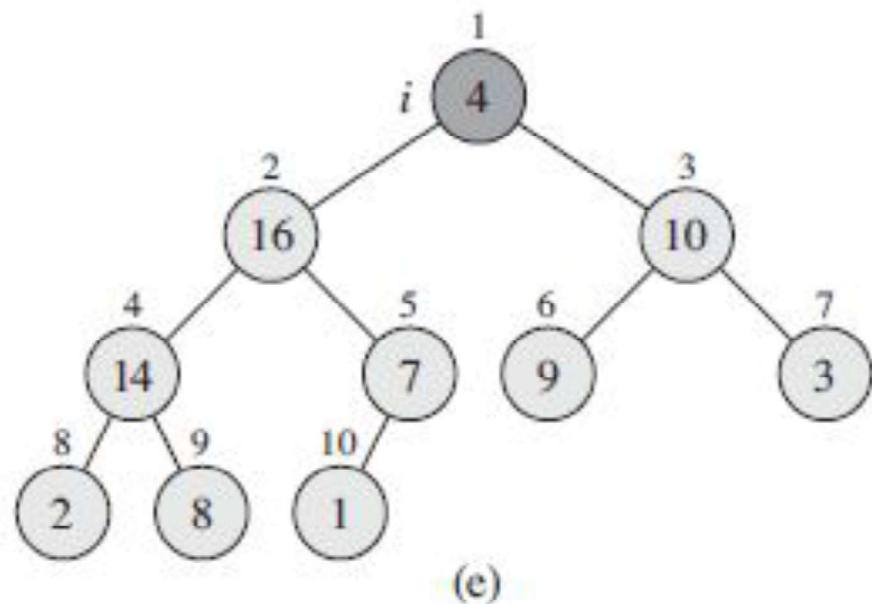

- 1  $A.heap-size = A.length$
- 2 **for**  $i = \lfloor A.length/2 \rfloor$  **downto** 1
- 3     **MAX-HEAPIFY**( $A, i$ )

## Example: Build Heap

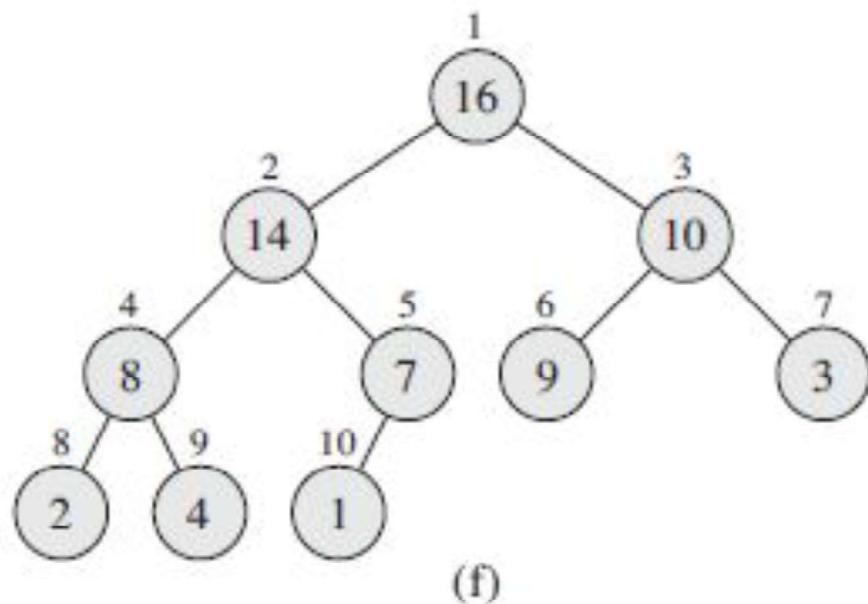

$A$  [ 4 | 1 | 3 | 2 | 16 | 9 | 10 | 14 | 8 | 7 ]

(e)

(f)

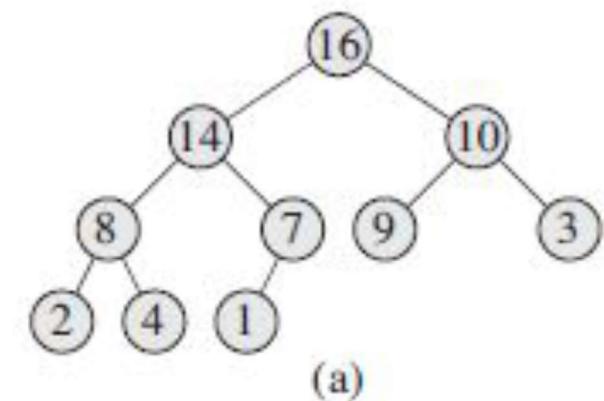

**Figure 6.3** The operation of `BUILD-MAX-HEAP`, showing the data structure before the call to `MAX-HEAPIFY` in line 3 of `BUILD-MAX-HEAP`. (a) A 10-element input array  $A$  and the binary tree it represents. The figure shows that the loop index  $i$  refers to node 5 before the call `MAX-HEAPIFY( $A$ ,  $i$ )`. (b) The data structure that results. The loop index  $i$  for the next iteration refers to node 4. (c)–(e) Subsequent iterations of the `for` loop in `BUILD-MAX-HEAP`. Observe that whenever `MAX-HEAPIFY` is called on a node, the two subtrees of that node are both max-heaps. (f) The max-heap after `BUILD-MAX-HEAP` finishes.

# The heapsort algorithm

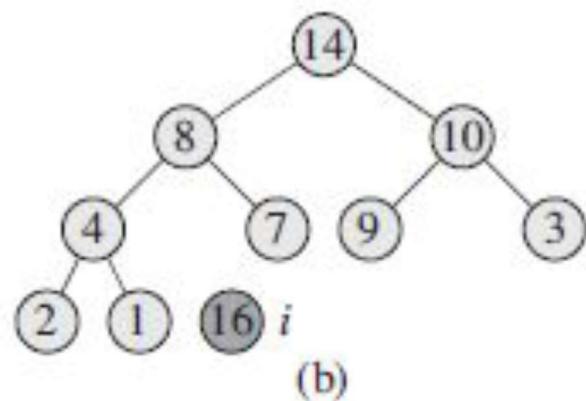

The heapsort algorithm starts by using `BUILD-MAX-HEAP` to build a max-heap on the input array  $A[1 \dots n]$ , where  $n = A.length$ . Since the maximum element of the array is stored at the root  $A[1]$ , we can put it into its correct final position by exchanging it with  $A[n]$ . If we now discard node  $n$  from the heap—and we can do so by simply decrementing  $A.heap-size$ —we observe that the children of the root remain max-heaps, but the new root element might violate the max-heap property. All we need to do to restore the max-heap property, however, is call `MAX-HEAPIFY( $A, 1$ )`, which leaves a max-heap in  $A[1 \dots n - 1]$ . The heapsort algorithm then repeats this process for the max-heap of size  $n - 1$  down to a heap of size 2. (See Exercise 6.4-2 for a precise loop invariant.)

**HEAPSORT( $A$ )**

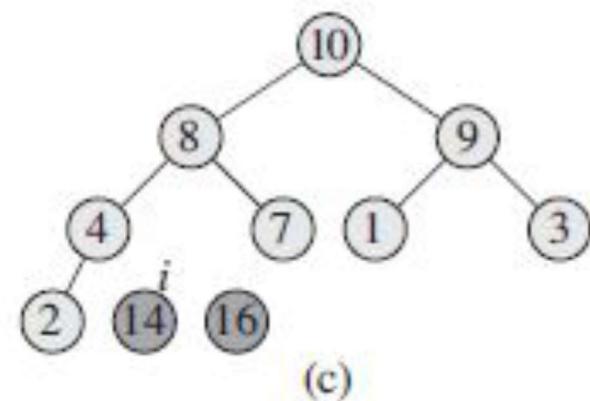

- 1   **BUILD-MAX-HEAP( $A$ )**
- 2   **for**  $i = A.length$  **downto** 2
- 3       exchange  $A[1]$  with  $A[i]$
- 4        $A.heap-size = A.heap-size - 1$
- 5       **MAX-HEAPIFY( $A, 1$ )**

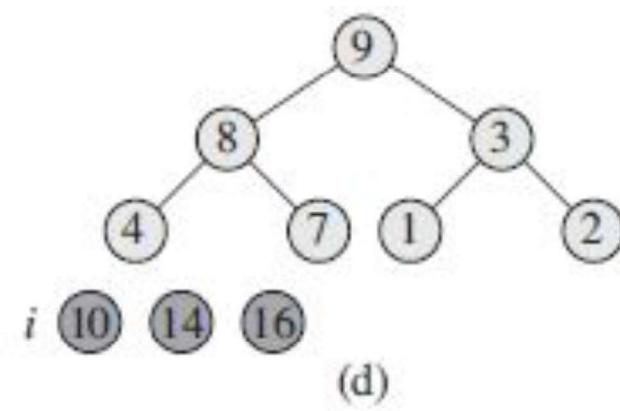

(a)

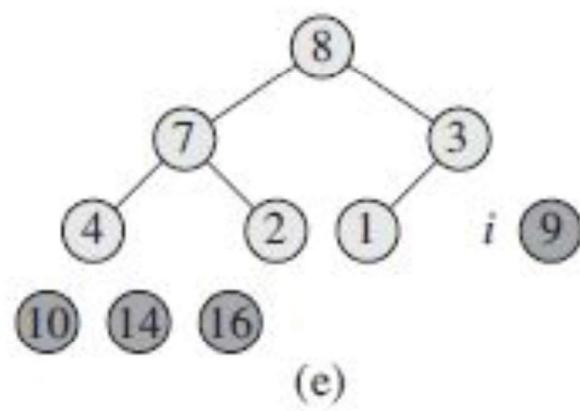

(b)

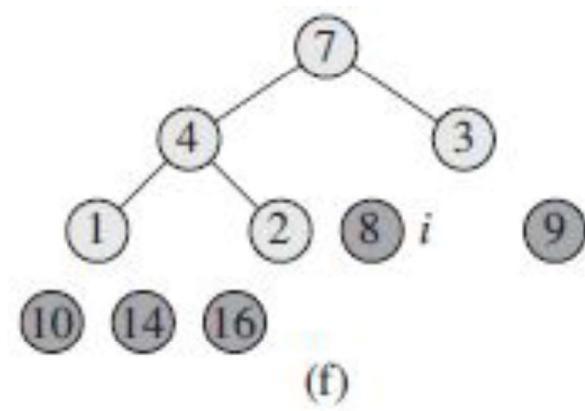

(c)

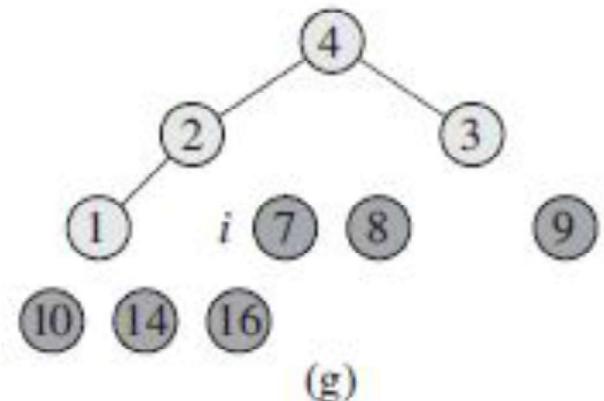

(d)

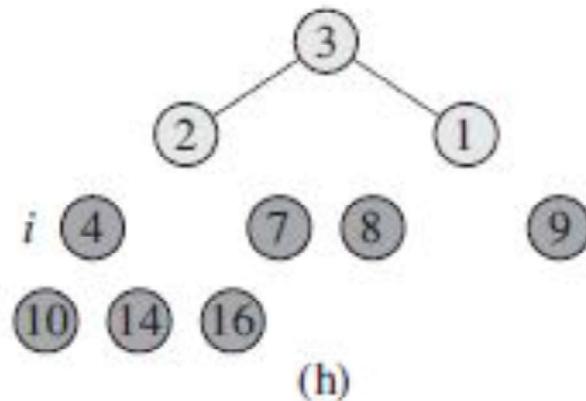

(e)

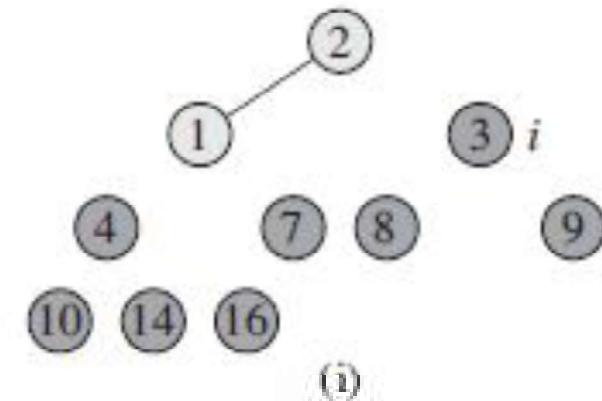

(f)

(g)

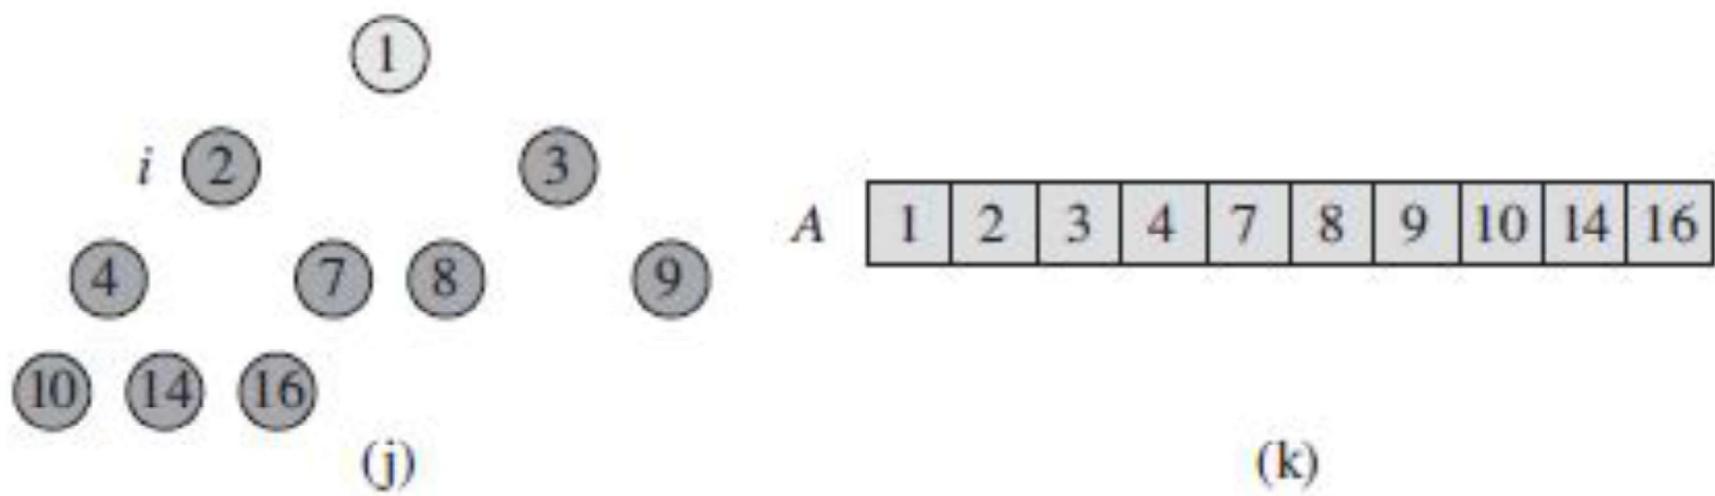

(h)

(i)

# Running Time

The HEAPSORT procedure takes time  $O(n \lg n)$ , since the call to BUILD-MAX-HEAP takes time  $O(n)$  and each of the  $n - 1$  calls to MAX-HEAPIFY takes time  $O(\lg n)$ .

**Figure 6.4** The operation of HEAPSORT. (a) The max-heap data structure just after BUILD-MAX-HEAP has built it in line 1. (b)–(j) The max-heap just after each call of MAX-HEAPIFY in line 5, showing the value of  $i$  at that time. Only lightly shaded nodes remain in the heap. (k) The resulting sorted array  $A$ .

# Priority queues

A *priority queue* is a data structure for maintaining a set  $S$  of elements, each with an associated value called a *key*. A *max-priority queue* supports the following operations:

**INSERT**( $S, x$ ) inserts the element  $x$  into the set  $S$ , which is equivalent to the operation  $S = S \cup \{x\}$ .

**MAXIMUM**( $S$ ) returns the element of  $S$  with the largest key.

**EXTRACT-MAX**( $S$ ) removes and returns the element of  $S$  with the largest key.

**INCREASE-KEY**( $S, x, k$ ) increases the value of element  $x$ 's key to the new value  $k$ , which is assumed to be at least as large as  $x$ 's current key value.

Now we discuss how to implement the operations of a max-priority queue. The procedure **HEAP-MAXIMUM** implements the **MAXIMUM** operation in  $\Theta(1)$  time.

### **HEAP-MAXIMUM( $A$ )**

```
1 return  $A[1]$ 
```

The procedure **HEAP-EXTRACT-MAX** implements the **EXTRACT-MAX** operation. It is similar to the **for** loop body (lines 3–5) of the **HEAPSORT** procedure.

### **HEAP-EXTRACT-MAX( $A$ )**

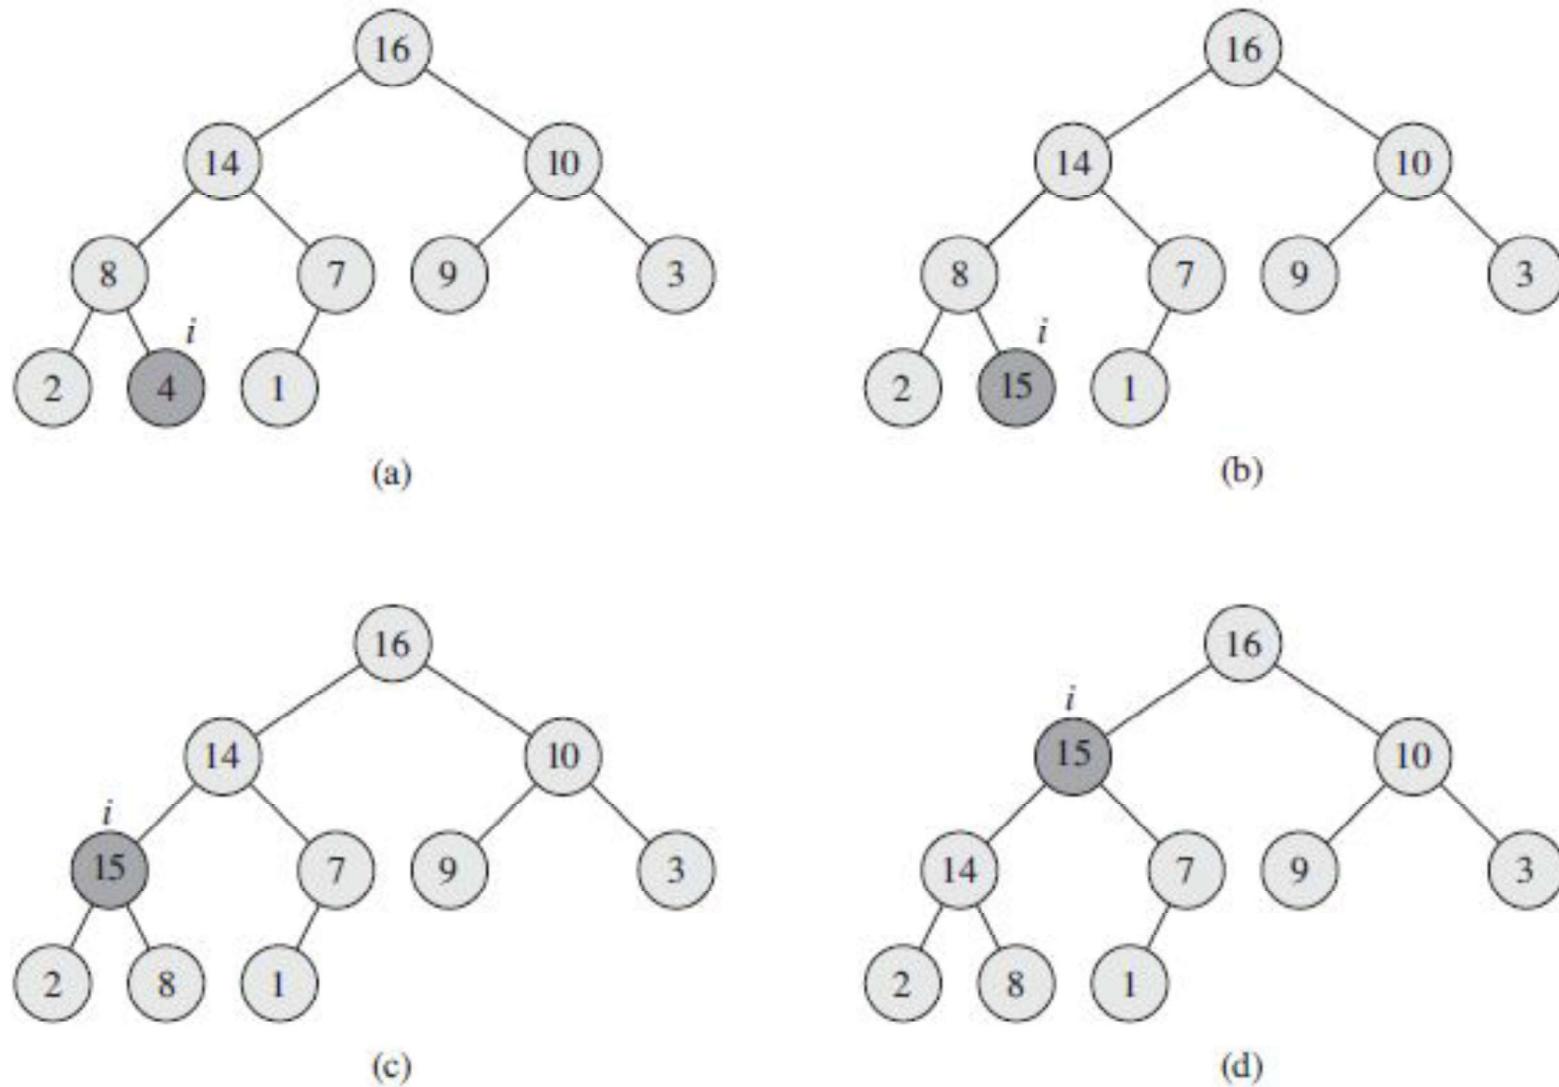

```
1 if  $A.\text{heap-size} < 1$ 
2     error "heap underflow"
3  $max = A[1]$ 
4  $A[1] = A[A.\text{heap-size}]$ 
5  $A.\text{heap-size} = A.\text{heap-size} - 1$ 
6 MAX-HEAPIFY( $A, 1$ )
7 return  $max$ 
```

**HEAP-INCREASE-KEY**( $A, i, key$ )

- 1   **if**  $key < A[i]$
- 2       **error** “new key is smaller than current key”
- 3     $A[i] = key$
- 4   **while**  $i > 1$  and  $A[\text{PARENT}(i)] < A[i]$
- 5       exchange  $A[i]$  with  $A[\text{PARENT}(i)]$
- 6        $i = \text{PARENT}(i)$

**MAX-HEAP-INSERT**( $A, key$ )

- 1    $A.\text{heap-size} = A.\text{heap-size} + 1$
- 2    $A[A.\text{heap-size}] = -\infty$
- 3   **HEAP-INCREASE-KEY**( $A, A.\text{heap-size}, key$ )

**Figure 6.5** The operation of HEAP-INCREASE-KEY. (a) The max-heap of Figure 6.4(a) with a node whose index is  $i$  heavily shaded. (b) This node has its key increased to 15. (c) After one iteration of the **while** loop of lines 4–6, the node and its parent have exchanged keys, and the index  $i$  moves up to the parent. (d) The max-heap after one more iteration of the **while** loop. At this point,  $A[\text{PARENT}(i)] \geq A[i]$ . The max-heap property now holds and the procedure terminates.

# Thank You
